IMPROVING DIMENSION REDUCTION VIA CONTOUR-PROJECTION

Hansheng Wang, Liqiang Ni and Chih-Ling Tsai

Peking University, University of Central Florida and University of California-Davis

Abstract: Most sufficient dimension reduction methods hinge on the existence of finite moments of the predictor vector, a characteristic which is not necessarily warranted for every elliptically contoured distribution as commonly encountered in practice. Hence, we propose a contour-projection approach, which projects the elliptically distributed predictor vector onto a unit contour, which shares the same shape as the predictor density contour. As a result, the projected vector has finite moments of any order. Furthermore, contour-projection yields a hybrid predictor vector, which encompasses both the direction and length of the original predictor vector. Therefore, it naturally leads to a substantial improvement on many existing dimension reduction methods (e.g., sliced inverse regression and sliced average variance estimation) when the predictor vector has a heavy-tailed distribution. Numerical studies confirm our theoretical findings.

Key words and phrases: contour-projection; dimension reduction; linearity condition; sliced average variance estimation; sliced inverse regression

1. Introduction

High dimensional data frequently encountered in applications poses a serious challenge for parameter estimation and statistical inference, especially in the presence of unknown nonlinear structures. One plausible solution is reducing the dimension without going through a parametric or nonparametric model fitting process. To this end, Li (1991) introduced the seminal work of sliced inverse regression (SIR), which has played a prominent role in dimension reduction. Since then, various dimension reduction methods have been proposed (e.g., sliced av-
average variance estimation (SAVE, Cook and Weisberg 1991), principal Hessian directions (pHd, Li 1992), and most recently contour regression (Li et al. 2005). See Cook and Ni (2005) for a recent review.

A common feature of the aforementioned dimension reduction methods is that they are model-free with assumptions on the marginal distribution of the predictor \( x \in \mathbb{R}^p \) instead of on the conditional distribution of the response \( y|x \). To exploit this information via the inverse regression approach, one often assumes that the predictor is elliptically distributed. However, this assumption does not guarantee that the predictor has finite first or second moments, which is required for the inverse regression or other dimension reduction methods (e.g., SIR, SAVE, and pHd). Even if those moments do exist, the heavy-tailed predictor may still seriously deteriorate the performance of the existing methods. The heavy-tailed distribution has been observed in many natural phenomena including financial, physical, and sociological fields. Hence, resolving this challenging task becomes important to further facilitate the use of existing dimension reduction methods.

Observations generated from the heavy-tailed distribution are sometimes viewed as outliers (see Hampel, Ronchetti, Rousseeuw, and Stahel, 1986). Therefore, one could explore the robust version of SIR for dimension reductions. For example, Gather et al. (2002) discussed the outlier sensitivity of SIR and Prendergast (2005) proposed to detect influential observations for SIR via influence functions. However, none of them studied dimension reductions for the heavy-tailed distribution. This motivated us to propose a contour-projection (CP) procedure which can lead to a substantial improvement on dimension reduction when the predictors have heavy-tailed distributions. Specifically, the CP approach projects the predictor vector onto a unit contour, which shares the same shape as the original density contour. The resulting predictor vector, namely CP-predictor, encompasses the direction and length of the original predictor vector and has finite moments of any order. The CP approach enables us to improve parameter estimations for heavy-tailed predictors. To utilize our findings, we focus on two widely used dimension reduction methods, SIR and SAVE.
The rest of this paper is organized as follows. Section 2 presents the basic idea of the \textit{contour-projection} approach and its properties. The utilization of the \textit{contour-projection} on dimension reductions is addressed in Section 3. Simulation studies are carried out in Section 4, and the results show that CP performs well for heavy-tailed predictors. Furthermore, a real example is given to illustrate the usefulness of CP. We conclude the paper with a brief discussion in Section 5.

2. Contour-Projection

We use the generic notation $S$ to denote a linear subspace of $\mathbb{R}^p$. For example, for a $p \times q$ matrix $A$, $S(A)$ denotes the linear space spanned by the columns of $A$. To capture the dependence between $y$ and $x$, it is assumed that there is a $p \times d$ matrix $\beta$ for some integer $d > 0$, such that

$$y \perp x | \beta^T x, \quad (2.1)$$

where “$\perp$” denotes independence. In other words, $\beta^T x$ summarizes all information $x$ has about $y$. We refer to $S(\beta)$ as the \textit{sufficient dimension reduction subspace} (SDR, Cook 1996). It is easy to see that any subspace $S \supset S(\beta)$ is also a SDR subspace. Therefore, it is only of interest to infer the “smallest” SDR subspace, which is referred to as the \textit{central subspace} and denoted by $S_{y|x}$. In the rest of article, we assume that $S_{y|x}$ exists with a basis being $\beta$ as defined in $(2.1)$. The notion of \textit{central subspace} is very helpful in exploratory analysis and data visualization. When $p$ is large, sufficient summary plots based on the \textit{central subspace} with dimension $d < p$ can be very informative for statistical modeling. Because $p = 1$ does not require dimension reduction, we consider $p > 1$ in the rest of the paper.

In this paper, we assume that the predictor $x$ follows an elliptically contoured (EC) distribution with the density (see Muirhead, 1982)

$$f_{\mu, \Sigma}(x) = |\Sigma^{-1/2}|f(||x - \mu||_\Sigma^2), \quad (2.2)$$

where $\mu \in \mathbb{R}^{p \times 1}$ and $\Sigma \in \mathbb{R}^{p \times p}$ are the parameters. The $\Sigma$ is a positive definite
matrix with \( \text{tr}(\Sigma) = p \) for identifiability, and \( ||t||_\Sigma^2 = t^\top \Sigma^{-1} t \) is a Mahalanobis distance. The elliptically contoured distribution is the most common assumption for the predictor in sufficient dimension reduction literature, partly because it ensures that a so-called linearity condition holds for the basis of central subspace, i.e. \( E(x|\beta^\top x) \) is a linear function of \( \beta^\top x \) (Li, 1991). The linearity condition connects the central subspace with inverse regression, which is one of the main venues for sufficient dimension reduction. It is worth noting that the EC condition implies the linearity condition when the second-order moment exists. In addition, the EC condition can still be satisfied when the second-order moment of the predictor does not exist. Moreover, even if the actual distribution departs from (2.2), it can be improved by either re-weighting methods (Cook and Nachtsheim, 1994) or through the multivariate Box-Cox transformation (Quiroz et al., 1996). A classical vs. robust Mahalanobis distance plot (DD plot) can serve as a diagnostic tool for elliptical symmetry (Olive, 2002).

The idea of the contour-projection is simple. Given \( \mu \) and \( \Sigma \), \( C = \{ x : ||x - \mu||_\Sigma^2 = 1 \} \) defines a unit contour, which shares the same shape as the predictor density as in (2.2). For any predictor \( x \), the CP procedure constructs a new predictor \( \tilde{x} = (x - \mu)/r \), by projecting \( x \) onto the unit contour \( C \), where \( r = ||x - \mu||_\Sigma \). The resulting \( \tilde{x} \) is bounded with finite moments of any order. Lemma 1, given below, shows some important properties of \( \tilde{x} \) and \( r \).

**Lemma 1.** Assume \( x \) has a density function as (2.2). Then, (1) \( E(\tilde{x}) = 0 \) and \( \text{cov}(\tilde{x}) = p^{-1} \Sigma; \) (2) letting \( \xi \in \mathbb{R}^{p \times q} \), \( q < p \), be any orthogonal matrix such that \( \xi^\top \xi = I_q \), we have \( E(\tilde{x}|\xi^\top \tilde{x}) = A \xi^\top \tilde{x} \), where \( A = \Sigma \xi (\xi^\top \Sigma \xi)^{-1} \); (3) \( \tilde{x} \) and \( r \) are mutually independent.

**Proof:** (1) Define \( u = \Sigma^{-1/2}(x - \mu) = (u_1, \cdots, u_p)^\top \), with density given by \( f(||u||^2) \). Then, \( \tilde{x} = \Sigma^{1/2}u/||u|| \). Because \( u_i \)'s are exchangeable, we have \( E(u_i||u||) = 0, E(u_i^2||u||) = E(u_j^2||u||), \) and \( E(u_iu_j||u||) = 0 \) for the given \( ||u|| \) with \( i \neq j \). These results together with \( \text{trace}\{E(uu^\top||u||^2)\} = 1 \) imply that \( E(\tilde{x}) = \Sigma^{1/2}E(u/||u||) = 0 \) and \( E\{\tilde{x}\tilde{x}^\top\} = \Sigma^{1/2}E(uu^\top/||u||^2) \Sigma^{1/2} = p^{-1} \Sigma. \)
(2) Let $\gamma = \Sigma^{1/2}\xi$, $P_{\gamma} = \gamma(\gamma^T\gamma)^{-1}\gamma^T$ be the orthogonal projection onto the subspace spanned by $\gamma$, and $Q_{\gamma} = I_p - P_{\gamma}$. We then have $E(Q_{\gamma}u|P_{\gamma}u, \|u\|) = 0$ and

$$E\left(\frac{u}{\|u\|}\left|P_{\gamma}u/\|u\|\right]\right) = E\left\{\left(\frac{P_{\gamma} + Q_{\gamma}}{\|u\|}\right)\left|P_{\gamma}u/\|u\|\right]\right\}
= P_{\gamma}u/\|u\| + E\left\{\left|u\right|^{-1}E(Q_{\gamma}u|P_{\gamma}u, \|u\|)\left|P_{\gamma}u/\|u\|\right]\right\}
= P_{\gamma}u/\|u\|.$$

Therefore, $E\{\tilde{x}|\Sigma^{1/2}\xi(\xi^T\Sigma \xi)^{-1}\xi^T \tilde{x}\} = \Sigma \xi(\xi^T\Sigma \xi)^{-1}\xi^T \tilde{x}$. Consequently, we have $E(\tilde{x}|\xi^T \tilde{x}) = A\xi^T \tilde{x}$ since $\Sigma^{1/2}\xi(\xi^T\Sigma \xi)^{-1} \in \mathbb{R}^{p\times q}$ is a full column rank matrix.

(3) This is a direct result of Theorem 1 in Cambanis et al. (1981).

Remark 1. Lemma 1 shows that Li’s (1991) linearity condition holds for the CP predictor. It also suggests that $\tilde{x}$ itself may contribute useful information on the central subspace, while the role of the length of the predictor $x$ can be secondary (see Section 3 for detailed illustrations).

In practice, both $\mu$ and $\Sigma$ are often unknown and need to be estimated from the data. To this end, Tyler (1987, p.245) proposed the simultaneous M-estimators for $\mu$ and $\Sigma$, which coincides with a simple iteratively estimating procedure motivated by Lemma 1. Specifically, let $\mu^{(m)}$ and $\Sigma^{(m)}$ be the estimates obtained after the $m$’th iteration. Because $E(\tilde{x}) = E\left(\frac{x-\mu}{\|x-\mu\|}\right) = 0$, which suggests that based on $(\mu^{(m)}, \Sigma^{(m)})$, $\mu^{(m+1)}$ can be obtained by

$$\mu^{(m+1)} = \left(\frac{1}{n} \sum_{i=1}^{n} \frac{1}{\|x_i - \mu^{(m)}\|_{\Sigma^{(m)}}}\right)^{-1} \left(\frac{1}{n} \sum_{i=1}^{n} \frac{x_i}{\|x_i - \mu^{(m)}\|_{\Sigma^{(m)}}}\right). \tag{2.3}$$

Subsequently, using the fact that $\text{cov}(\tilde{x}) = p^{-1}\Sigma$, $\Sigma^{(m+1)}$ can be obtained by first computing

$$\Sigma^{(m+1)} = \frac{1}{n} \sum_{i=1}^{n} \frac{(x_i - \mu^{(m)})(x_i - \mu^{(m)})^T}{\|x_i - \mu^{(m)}\|_{\Sigma^{(m)}}^2}, \tag{2.4}$$
and then re-scaling $\Sigma^{(m+1)}$ so that its trace equals $p$.

It seems natural to obtain parameter estimators of $\mu$ and $\Sigma$ by iterating (2.3) and (2.4) until the algorithm converges. However, Tyler (1987) pointed out that the convergence and consistency of simultaneous fixed-point solutions is still an open question. Under some regularity conditions, Tyler (1987) showed that if $\mu^{(m)}$ is a consistent estimate of $\mu$, the fixed point solution of (2.4) alone uniquely exists and reaches a consistent estimate of $\Sigma$ (see Frahm (2004) for detailed discussions). This motivates us to propose a hybrid estimator that combines the fixed-point solution and one-step reweighting algorithm given below.

1. Let $\hat{\mu}_0$ be the componentwise median and let $\hat{\Sigma}_0$ be the sample covariance matrix.
2. Let $\mu^{(m)} = \hat{\mu}_0$ in (2.4). The fixed point solution is $\hat{\Sigma}_1$.
3. Plug $(\hat{\mu}_0, \hat{\Sigma}_1)$ into (2.3) to obtain $\hat{\mu}_1$.
4. Let $\mu^{(m)} = \hat{\mu}_1$ in (2.4). The fixed point solution is $\hat{\Sigma}_2$.
5. Plug $(\hat{\mu}_1, \hat{\Sigma}_2)$ into (2.3) to obtain $\hat{\mu}_2$.

The above procedure not only avoids the convergence issue of (2.3) but also facilitates the computation speed. Furthermore, the consistent estimate $\hat{\mu}_0$ of $\mu$ leads to that $\hat{\mu}_2$ and $\hat{\Sigma}_2$ are consistent, which perform well in simulation studies (see Section 4).

Remark 2. In multivariate distributions, there is considerable literature on robust location and dispersion estimators (e.g., minimum covariance determinant (MCD) and minimum volume ellipsoid (MVE) methods, see Maronna and Zamar (2002)). In addition, the function cov.rob in the package MASS (Venables and Ripley, 2006) of R provides robust estimators of location and dispersion parameters. Once those estimators’ theoretical and computational issues have been well resolved, they may also be employed to estimate $\mu$ and $\Sigma$ in contour-projection.
3. Dimension reduction via contour-projection

To make \textit{contour-projection} an effective SDR technique for the regression, we build up a connection between the dimension reduction subspaces before and after \textit{contour-projection} via the following lemma.

\textbf{Lemma 2.} Suppose $\xi$ is a basis of $S_{y|x}$. Then, $y \perp \tilde{x}|\xi^\top \tilde{x}$.

\textit{Proof:} Let $F(\cdot)$ be a generic cumulative distribution function. Suppose $\xi$ is a basis of $S_{y|x}$. Then, $y \perp x|\xi^\top x$ which is equivalent to $y \perp (\tilde{x}, r)|\xi^\top x$. Moreover, $y \perp (\tilde{x}, r)|(\xi^\top \tilde{x}, r)$ which leads to $y \perp \tilde{x}|(\xi^\top \tilde{x}, r)$. Hence, for any scalar $a$,

$$F_{y|\tilde{x}}(a) = \mathbb{E}_r[F_{y|\tilde{x}, r}(a)] = \mathbb{E}_r[F_{y|(\xi^\top \tilde{x}, r)}(a)] = F_{y|\xi^\top \tilde{x}}(a).$$

Consequently, $y \perp \tilde{x}|\xi^\top \tilde{x}$ (compare Cook, 1998, pp. 63, 64, and 106), and the proof is completed.

\textit{Remark 3.} Lemma 2 indicates that one may apply CP predictor $\tilde{x}$ to gain information of the central subspace $S_{y|x}$. To further elucidate this finding, we consider the following multi-index model

$$y = g(\beta^\top x, \epsilon), \quad (3.1)$$

where $g(\cdot)$ is some unknown function and $\epsilon$ is a random noise independent of $x$. Because $x = \mu + r\tilde{x}$, model (3.1) can be expressed as

$$y = \tilde{g}(\beta^\top \tilde{x}, r, \epsilon), \quad (3.2)$$

for some unknown function $\tilde{g}$, where $(\epsilon, r)$ is independent of $\tilde{x}$. Therefore, it is possible to find $\beta$ via (3.2) rather than (3.1).

\textit{Remark 4.} For the sake of simplicity, one can exclude $r$ from (3.2) to compute $\beta$. However, this may lead to the identification problem. For example, assume that
\( x \) follows a \( p \)-dimensional standard normal distribution with \( \Sigma = I, \ p > 2, \) and

\[
y = \sum_{i=2}^{p} x_i^2 + \epsilon = r^2 \sum_{i=2}^{p} \tilde{x}_i^2 + \epsilon = r^2 - \tilde{x}_1^2 + \epsilon = r^2(1 - \tilde{x}_1^2) + \epsilon, \tag{3.3}
\]

where \( \epsilon \) is an independent noise. As a result, both \( S(e_1) \) and its orthogonal complement \( S_{y|x} \) are dimension reduction subspace in \( \tilde{x} \) scale, where \( e_1 \in \mathcal{R}^p \) is a vector with the first component being 1, and the others being 0. Therefore, we recommend including \( r \) in the analysis and also comparing the results from dimension reduction methods with and without contour projection.

The SIR and SAVE are among the most popular dimension reduction methods. We next explore the applications of SIR and SAVE on dimension reductions via the CP predictor. In regression analysis, Li (1991) proposed a sliced inverse regression approach for dimension reduction, which implicitly assumes that the first two moments of \( x \) exist. In addition, SIR requires the linearity condition: \( \text{E}(x|P_\beta x) \) is a linear function of \( P_\beta x \), where \( \beta \) is a basis of \( S_{y|x} \). To find the central subspace, Li (1991) considered the standardized predictor \( z \) with zero mean and identity covariance matrix. Under the linearity condition, \( \text{E}(z|y) \in S_{y|z} \), thus \( M_{sir} = \text{cov}(\text{E}(z|y)) \subseteq S_{y|z} \). When \( y \) is discrete, it is straightforward to obtain a sample version of \( M_{sir} \). If \( y \) is continuous, we discretize \( y \) first by partitioning the range of \( y \) to a few slices. If \( \text{dim}(S_{y|z}) = d \), then the \( d \) eigenvectors corresponding to the largest \( d \) eigenvalues of \( \hat{M}_{sir} \) constitute an estimated basis of \( S_{y|z} \). Afterwards, we transform the central subspace back to the original \( x \)-scale via \( S_{y|x} = \text{cov}(x)^{-1/2}S_{y|z} \).

In practice, however, an elliptically contoured predictor may not have a finite second moment even though it satisfies the linearity condition. In this case, SIR is not applicable for dimension reduction. This motivated us to employ contour-projection to overcome this issue, since the CP predictor has finite moments of any order. Based on \( \tilde{x} \) and assuming \( \beta \) is an orthogonal basis, we then apply the linearity condition given in Lemma 1 to obtain

\[
\text{E}(\tilde{x}|y) = \text{E}[\text{E}(\tilde{x}|(\beta^T \tilde{x}, y))|y] = \text{E}[\text{E}(\tilde{x}|\beta^T \tilde{x})|y] = \Sigma \beta (\beta^T \Sigma \beta)^{-1}\text{E}[\beta^T \tilde{x}|y].
\]
Therefore, under (2.2), $\Sigma^{-1}E(\tilde{x}|y) \in \mathcal{S}_{y|x}$, which suggests a direct application of SIR on $\tilde{x}$ is warranted, and is referred to as contour-projected SIR (CP-SIR). Accordingly, the non-identifiability of $\mathcal{S}_{y|\tilde{x}}$ does not affect the validity of CP-SIR.

In the last decade, SIR has been used successfully in many applications. However, it fails in a strictly symmetric case, e.g., $y = (\beta^T z)^2 + \epsilon$, where $(z, \epsilon)$ are multivariate independent standard normal. To this end, Cook and Weisberg (1991) proposed SAVE, which may recover some of the information that could be overlooked by SIR. Let $\eta$ be a basis of $\mathcal{S}_{y|z}$. Then, for the elliptically distributed predictor, Cook and Weisberg (1991) found that

$$w_y I_p - \text{cov}(z|y) = P_\eta[w_y I_p - \text{cov}(z|y)]P_\eta,$$

where the scalar $w_y$ is a function of $y$ that depends on the distribution of $x$. Since $E(w_y) = 1$, $w_y$ varies from different values of $y$ about 1. Empirical results indicate that a SAVE kernel matrix $M_{\text{save}} = E[(I_p - \text{cov}(z|y))^2]$ can be utilized to estimate $\mathcal{S}_{y|x}$ in a way similar to the procedure for $M_{\text{sir}}$ (see Cook and Weisberg 1991).

To employ the CP predictor $\tilde{x}$, define $v = \Sigma^{-1/2} \tilde{x}$ and let $\gamma = \Sigma^{1/2} \beta$ denote a basis of a dimension reduction subspace of the regression of $y$ on $v$. Since $v$ is uniformly distributed on a unit hypersphere, we have $E(v|y) \in \mathcal{S}(\gamma)$, $E(v|P_\gamma v) = P_\gamma v$, and $\text{cov}(v|P_\gamma v) = (1 - \|P_\gamma v\|^2)Q_\gamma/(p-d)$. It is easy to see that $\text{cov}(v|y) = u_y Q_\gamma + P_\gamma \text{cov}(v|y)P_\gamma$, or

$$u_y I_p - \text{cov}(v|y) = P_\gamma[u_y I_p - \text{cov}(v|y)]P_\gamma,$$

where $u_y = E(1 - \|P_\gamma v\|^2|y)/(p-d)$ and $E(u_y) = 1/p$. This motivates us to adopt the SAVE approach to estimate the central subspace via a kernel matrix $E[(I_p/p - \text{cov}(v|y))^2]$, which is equivalent to applying SAVE on $\tilde{x}$. We name this procedure as contour-projected SAVE (CP-SAVE).

4. Simulations and a Real Example
In this section, we employ the hybrid estimation procedure introduced in Section 2 to estimate the location and dispersion parameters. Furthermore, we adopt Weisberg’s (2002) \textit{dr} package in \textit{R} to implement SIR and SAVE and then make comparisons.

4.1 Comparison of Estimates

To illustrate the applications of CP-SIR and CP-SAVE, we consider the following two models

Model I: \( y = \frac{x_1}{0.5 + (x_2 + 1.5)^2} + 0.2\epsilon, \)

Model II: \( y = (x_1 + 0.5)^2 + x_2 + 0.2\epsilon, \)

where \( \epsilon \) was simulated from a standard normal distribution. For each model, we generated 500 data sets with the sample sizes \( n = 100, 200, 300, \) and \( 400. \) Furthermore, \( x = (x_1, \cdots, x_{10})' = w/\sqrt{v_{df}/df}, \) where \( w \in \mathcal{R}^{10} \) is a standard multivariate normal distribution and \( v_{df} \) is a chi-square distribution with degrees of freedom \( df (df = 1, 3, 5, \infty). \) As a result, \( x \) follows a multivariate \( t \) distribution (see Lange et al. 1989). Specifically, they represent the situations where the tail of the predictor is extremely heavy so that moments do not exist \((df = 1), \) the predictor has a heavy tail with finite first order moment \((df = 3), \) the predictor has a heavy tail with finite second order moment \((df = 5), \) and the tail of the predictor is not heavy at all \((df = \infty) \) that corresponds to a multivariate normal distribution of \( x_i). \)

The \textit{central subspace} associated with both models is given by \( S(\beta), \) where \( \beta = \{e_1, e_2\} \) and \( e_l \in \mathcal{R}^p \) is a vector with the \( l \)-th component being 1, and the others being 0. For each data set, SIR, CP-SIR, SAVE, and CP-SAVE were applied with the number of slices set up at 5. Without the loss of generality, let \( \hat{\beta} \) denote the estimated basis obtained from any of the four inverse regression approaches. The estimation accuracy of the \textit{central subspace} is measured by a distance \( \Delta = \|P_{\beta} - P_{\hat{\beta}}\| \) (see Li, et al., 2005), where \( \|\cdot\| \) is the maximum singular value of a matrix.
For Model I, Table 1 reports the average of $\Delta$ for estimates obtained from SIR and CP-SIR, respectively, in 500 realizations. Although SIR deteriorates with heavier tails, CP-SIR holds much higher accuracy. Because the constant $1.5$ in the denominator of model I is relatively large, the results from SAVE methods are less satisfactory than those in Table 1. In this situation, however, the unreported results showed that CP-SAVE is superior to SAVE.

Table 1: The average of $\Delta$ from 500 realizations for model I when the predictors are generated from multivariate $t$ distributions.

As discussed in Section 3, SAVE is usually more comprehensive than SIR in the estimation of the central subspace. For example, if the constant $1.5$ in model I gets closer to 0, SIR gradually loses the capability to detect the direction associated with $x_2$, while SAVE still can. Model II is another example where SAVE can be sharper than SIR. Table 2 reports the average of $\Delta$ for estimates obtained from SAVE and CP-SAVE for model II, which corroborates the benefits of contour-projection. Next, we show the effect of contour projection on the parameter inference.

4.2 Comparison of inferences

Suppose that \( \hat{\eta}_i \) is the \( i \)-th eigenvector of \( \hat{M}_{\text{sir}} \) with corresponding eigenvalue \( 0 < \hat{\lambda}_i < 1 \). Then, \( \hat{\beta}_i = \text{cov}(x)^{-1/2} \hat{\eta}_i \) is the estimate of \( \beta_i \) (the \( i \)-th column of \( \beta \)) in the central subspace \( S_y|x \). Under the null hypothesis, \( H_0 : e_i^T \beta_i = 0 \), Chen and Li (1998) showed that the test statistic \( n(e_i^T \hat{\beta}_i)^2 \frac{\hat{\lambda}_i}{(1-\hat{\lambda}_i)} [e_i^T \text{cov}(x)^{-1} e_i]^{-1} \) follows an asymptotic chi-squared distribution with 1 degree of freedom. The above result can be analogously applied to CP-SIR.

To make comparisons, we revisit model I. For the sake of simplicity, we only consider \( x \) to be the multivariate \( t \) distribution with \( df = 3 \) and sample size \( n \) to be 300. Under the null hypothesis \( H_0 : e_3^T \beta_1 = 0 \), the p-values should be uniformly distributed. Figure 1 depicts the uniform quantile-quantile plot of 500 p-values obtained from SIR and CP-SIR, respectively. Apparently, the CP-SIR performs better than SIR. Furthermore, the \( x \) with \( df = 1 \) yields more conspicuous contrast than that of \( df = 3 \), which is not presented here.

Analogously, we conducted the test to assess the null hypothesis, \( H_0 : e_3^T \beta_2 = 0 \), and obtained the similar results to those given above. Next, we assess the sensitivity of the contour projection against the non-elliptical predictors.

4.3 Non-elliptical predictors

Although SIR and SAVE are not particularly sensitive to the violation of the elliptical assumption, it is still of interest to evaluate the performance of CP under a non-elliptically symmetric distribution. To this end, we consider the same simulation settings as those in Section 4.1, except that the random variable $w$ was generated from a uniform distribution on $[-\sqrt{3}, \sqrt{3}]^{10}$. The simulation results are similar to those in Section 4.1. For example, Table 3 shows that CP-SIR is superior to SIR for the heavy-tailed predictors. Hence, CP is not sensitive to the elliptical assumption.

Table 3: The average of $\Delta$ from 500 realizations for model I when the predictors are generated from multivariate uniform distributions.

4.4 A real example

To illustrate the effectiveness of the CP approach, we consider the data set created by CCER (Center for China Economic Services). The CCER database is one of most authoritative and widely used stock market databases on the China stock market (http://www.ccerdata.com/). The objective of this study is to derive an index, which can be used for predicting the firm’s next year’s earning. To this end, the response variable ($y_i$) is taken as the next year’s return on equity (ROE$_y$), while the predictor vector ($x_i$) includes the firm’s current year’s return on equity (ROE$_x$), log-transformed asset (ASSET), profitability margin (PM), sales growth rate (SALES), leverage level (LEV), and asset turnover ratio (ATO). In addition, the data contains yearly informations of firms from 1995 to 2004. The sample size of firms per year ranges from the minimum 283 (Year 1995) to the maximum 1172 (Year 2003). Moreover, the kurtosis measures indicate all predictors have very heavy tailed distributions.
For each of nine years’ data sets, we employ both SIR and CP-SIR with the same number of slices (5) as used in the simulation studies. For the sake of illustration, we only reported the most important direction estimate identified by SIR and CP-SIR, respectively, in each year. As a result, we obtained the nine most important direction estimates of SIR and CP-SIR. Figure 2 depicts the absolute value of the estimated coefficient for each of the six predictors across nine years’ data sets. We found that the CP-SIR estimates yield much less variabilities than those of SIR estimates (except for the predictor PM). In sum, CP-SIR should be considered when the predictor has a heavy-tailed distribution.

5. Conclusion

In this article, we propose a contour-projection procedure and then employ it to improve inverse regression methods for dimension reduction. We also present theoretical properties and Monte Carlo results, showing that SIR and SAVE can be improved substantially via the CP approach. However, this improvement is not limited to SIR and SAVE. We may extend the application of CP to other inverse regression approaches if the predictor has an elliptically contoured distribution. Possible gains of CP on recently developed approaches (e.g. Xia et al. 2002, Yin and Cook 2005) are under consideration.

Acknowledgements

We are grateful to the Editor, the Associate Editor, and the Referees for their valuable comments and constructive suggestions, which led to a substantial improvement of this manuscript. We are also grateful to Dr. Gabriel Frahm for some helpful discussions.
